\section*{BACKGROUND: WHY CARE ABOUT SOILING AND SNOW?}

\textbf{WHAT IS SOILING:} The accumulation of naturally occurring particles on solar panels is commonly referred to as soiling. This may include fine sand, soot, pollen, bird droppings, and, in colder climates, snow.

\textbf{WHY CARE ABOUT SOILING:} Soiling on PV modules presents a significant loss of efficiency, due to reduced transmission and also potentially due to shading effects on the system. Results related to PV in cold climate and snow are relatively scarce as PV has only recently gained market shares in such regions.

\section*{EFFECT OF SNOW COVERAGE}

Figure 2. The topmost string has one partly snow covered module (highlighted), which results in a reduction of the effect of the whole string by 70\%. Production losses due to partly snow covered modules are particularly relevant in spring time in cold climates, when snow is still present while insolation is high.

\section*{EFFECT OF PANEL ORIENTATION}

Modelling in SPICE shows that the 70\% reduction in production is as expected for a vertical panel where the bottom half is covered in snow. It is also clear from the modelling that horizontal orientation is preferable to a vertical orientation of the solar module. Although the same amount of snow covers a larger fraction of the panel when it is in a horizontal position, the power output is actually larger due to the series connection configuration of the cells.

\section*{THE SOILING-PRECIPITATION CORRELATION}

Figure 4. Daily precipitation data from eKlima and measured dust densities accumulated at the normal and anti-soiling coated glass samples. The values for the dust densities are scaled to [mg/m\textsuperscript{2}]. Note that the rainfalls do not wash the modules perfectly clean.

\section*{QUANTITATIVE ASSESSMENT OF DUST IN THE FIELD}

A quantitative measurement of dust is performed by drying module glass with a cloth. The glass sample and the cloth were both weighted before and after drying to validate the method. Both dry cleaning and wet cleaning was tested, both giving clean surfaces as determined by visual inspection and transmission measurements. The dry cleaning gave the most consistent and reproducible results. The method is highly relevant for quantitative assessment of dust on modules in the field.

\section*{SMALL DUST DENSITIES: LINEAR CORRELATION WITH TRANSMISSION}

Figure 5. Soiling experiment on small module glass samples with and without antisoiling coating. Soiling levels at Kjeller, Norway were found to give transmission reductions of 1-2\%, which are considered to be low. A linear correlation is found between transmission and dust density.
